Samenvatting

Executive Summary

The main conclusions from this report are listed below for each Chapter.

Introduction

- On instruction of the Minister of Economic Affairs and Climate Policy NAM has prepared 10 Hazard and Risk Assessments (HRAs) since 2012. This year is the first time the HRA is prepared by TNO.
- NAM delivers the reservoir pressure and subsidence forecasts. Reservoir pressure forecasts were delivered to TNO on February 15th as input for the HRA.

Reservoir and Pressure Modelling

- The minister has requested assessments based on a single Operational Strategy (OS) and for two temperature scenarios: an average and a cold gas year 2021/2022. For these scenarios demand profiles have been provided to NAM (GTS-raming 2021).
- The Operational Strategy is in line with OS2 as proposed by NAM last year in the HRA2020. The OS2 start-up sequence applies until April 1st 2022. Thereafter, production volumes are equally distributed over regions South-East and South-West.
- Forecasted reservoir pressures at the start of gas-year 2021/2022 are slightly higher than forecasted for the HRA2020 (based on GTS-raming 2020). This is due to higher than average ambient temperatures in 2020 and additional measures to reduce Groningen production volume.
- Forecasted pressures in the active production regions based on the new estimate (GTS-raming 2021) are slightly lower in the period 2025-2027 than forecasted in 2020 (based on GTS-raming 2020). This is the result of the small additional production volumes associated with the minimum flow requirement to ensure availability of gas production capacity. The pressure differences are negligible after 2032.

Subsidence

- The compaction/subsidence model was calibrated using results from 16 levelling campaigns spanning from 1964 to 2018.
- Subsidence forecasts were made for 2025, 2031 and 2050 based on GTS-raming 2021.
- In 2031 around 42 cm of surface subsidence (since start of production) is expected in the deepest point of the subsidence bowl, with a P95 uncertainty range up to 3 cm.

1 Introduction

1.1 Previous Hazard and Risk Assessment Reports

Since 2012 NAM has prepared Hazard and Risk Assessments (HRA) for different production scenarios. Table 1.1 provides an overview of these HRA reports. Currently, the hazard and risk assessment for induced earthquakes in Groningen is updated annually. The update is initiated each year with an expectation letter from the Minister of Economic Affairs and Climate Policy sent on the 1st February. Six weeks later a hazard and risk assessment based on the instructions and production scenarios presented in this expectation letter would be submitted to SodM and the ministry. In the gas production profile, the actual production until the previous 1st January is used and for the remainder of the gas-year of publication of the report (from 1st January to 1st October) the production is based on the latest ministerial decision.

In figure 1.1 the annual production rates for the previous production profiles; (1) Coalition Agreement, (2) Basispad Kabinet March 2018 Letter, (3) Basispad Kabinet Expectation May 2018 Letter, (4) Expectation Letter February 2019, (5) Expectation Letter February 2020 and (6) Expectation Letter February 2021 are compared. The comparison is shown in this figure for cold, average and warm year gas demand.

1.2 Expectation Letter (verwachtingenbrief) 2021

In accordance with article 52c of the Mining Law, NAM proposed in previous HRA reports two operational strategies based on the premises for these strategies contained in the expectation letter. Due to the very low remaining production, differences in the operational strategy will only have a very minor impact on hazard and risk. The assessment of risk and building damage will in the coming years be dominated by the equilibration of reservoir pressure between the North-Western area and the South-Eastern area of the field. In this report the development of reservoir pressure and subsidence will be presented. The expectation letter received by NAM on 1st February 2021 has been attached to this report as Appendix A.

The expectation letter also describes the maps, graphs and tables to be included in this report. In order to present a clear analysis additional maps, graphs and tables have been included in this report when required for clarity. The forecast for reservoir pressure has been requested to be presented based on gas-years. Gas-years are the 12-month period starting at 1st October. The gas-year 2021/2022 is the period from 1st October 2021 up to and including 30st September 2022. Gas-years are used to avoid the high gas demand winter period to be split over two reporting periods. The assessment of subsidence included in this report uses calendar years to be in line with other subsidence reports.

1.3 TNO SDRA – Seismische Deigings- en Risicoanalyse

As part of the wider program to remove NAM from the Groningen earthquake dossier, TNO has taken over the assessment of hazard and risk from NAM. TNO has built their own modelling tool for the assessment of hazard and risk in Groningen (de TNO "Modellentrein") and will use this for the preparation of the Hazard and Risk Assessment 2021.

NAM has delivered the forecasts for reservoir pressure to TNO for their Hazard and Risk Assessment on 15th February 2021 and confirmed on 19th February that the assurance had been completed successfully. Reservoir pressure predictions have been prepared for input into the Hazard and Risk Assessment based on two production scenarios; a scenario for gas production during a cold ambient temperature year and for an average ambient temperature year. Additionally, an operability check has been done for a warm ambient temperature year.

Figure 1.1 Comparison of the production profiles:

- 1. Coalition Agreement (Regeerakkoord) (10/10/2017),
- 2. "Basispad Kabinet" from Kamerbrief (29/3/2018) in blue (Ref. 24),
- 3. "Basispad Kabinet" from the Expectation Letter (verwachtingenbrief) (2/5/2018) in red (Ref. 26)
- 4. Production profile GTS-raming 2019 in green (Ref. 27)
- 5. Production profile GTS-raming 2020 (Ref. 28) and
- Production profile GTS-raming 2021.
 For GTS-raming 2020 and GTS-raming 2021, th eproduction profiles for a warm gas-year are shown in blue. Those for average and cold temperature gas-year in green and red respectively.

Table 1.1Overview of the Hazard and Risk Assessments prepared by NAM.

2 Reservoir and Pressure Modelling

Modelling the pressure in the Groningen gas reservoir forms the starting point for both the seismic hazard and risk assessment as well as the subsidence forecast. The future pressure distribution in the reservoir depends on the amount of gas produced and on how this production is regionally distributed.

2.1 Production: Demand profiles GTS-raming 2021

The Ministry of Economic Affairs and Climate Policy provided demand profiles for Groningen gas with the Expectation Letter (Verwachtingenbrief - Appendix A) sent to NAM on the 31st of January 2021. The future demand for Groningen-quality gas has been determined by GTS, incorporating the latest knowledge around nitrogen blending capacity, conversion in the L-gas market, export requirements etc. Accounting for the contributions of UGS Norg and PGI Alkmaar results in the net Groningen production profiles. For gas-year 2021/2022 daily demand profiles have been provided based on temperature profiles of the last 30 gas-years. Three reference years were chosen, for which longer term daily as well as monthly demand profiles have been supplied. These reference years correspond to the temperature profiles of gas-years 1996 (cold year), 2012 (average year), and 2007 (warm year).

The seismic hazard and risk assessment is performed for two scenarios, based on (i) gas demand in the average temperature scenario, and (ii) gas demand for a cold gas year 2021/2022 followed by average years. These two demand profiles are used to simulate subsurface pressures and are plotted in Figure 2-1.

Figure 2-1: Groningen field monthly gas production according to GTS-raming 2021. The cold temperature scenario applies to gas-year 2021/2022 only.

2.2 Spatial distribution of production

2.2.1 Production regions

In Article 1.3a.1 of the Mining Regulations ("Mijnbouwregeling"), the Groningen production regions ("clusters") are defined as follows:

- a) Bierum: production location Bierum
- b) Eemskanaal: production location Eemskanaal
- c) East-Central ("Centraal-Oost"): production locations Amsweer, Schaapbulten, Oudeweg, Siddeburen, and Tjuchem
- d) South-East ("Zuidoost"): production locations De Eeker, Scheemderzwaag, and Zuiderpolder
- e) South-West ("Zuidwest"): production locations Kooipolder, Slochteren including Froombosch, Spitsbergen, Tusschenklappen including Sappemeer, and Zuiderveen
- f) Loppersum: production locations De Paauwen, Leermens, Overschild, 't Zandt, and Ten Post

Figure 2-2: Production locations and regions.

The production locations are shown in a different color for each region in Figure 2-2. Production from the Loppersum clusters stopped in February 2018, following the instruction from the Minister of Economic Affairs and Climate Policy. As decided in the 2020 Vaststellingsbesluit (Article 3), clusters Bierum, Eemskanaal, and production location Siddeburen are no longer part of the operational strategy and remain closed in.

2.2.2 Start-up sequence

In 2020 the minister instructed NAM to follow Operational Strategy 2. In this Operational Strategy gas is produced preferentially from the South-East. If more production is required production locations in the South-West are first added, followed by the Central-East region when required. The operational strategy is practically implemented by the use of a start-up sequence; the order in which the production locations are taken into production, when more production from the field is required. The start-up sequence for this Operational Strategy is given in Table 2-1.

From April 2022 onwards, when the Zuidbroek nitrogen installation will be operational, the role of the Groningen field changes and the start-up sequence from Table 2-1 no longer applies. Groningen will

then operate on minimum flow in order to maintain on stand-by such that it can perform its back-up function for extreme circumstances. This is further discussed in the Operational Strategy document.

| Start-up group | OS2 |
|----------------|-----|
| EKR/SZW/ZPD | 1 |
| SPI/ZVN | 2 |
| SAP/TUS | 3 |
| FRB/KPD/SLO | 4 |
| SCB/OWG | 5 |
| AMR/TJM | 6 |

 Table 2-1:
 Production start-up list for the current Operational Strategy (OS2).

For pressure forecasting it is assumed that from April 2022 onwards equal volumes are produced from regions South-East (EKR/SZW/ZPD) and South-West. In South-West, production locations SPI, ZVN, and TUS/SAP will be operational. Start-up groups 4, 5, and 6 from Table 2-1 are no longer needed.

2.3 Modelling setup

An Integrated Production System Model is used for forecasting. In this set-up, the dynamic reservoir model in MoReS is coupled to the surface network model in Genrem. As last year, dynamic reservoir model V6 is used (Ref. 32). The average deviation in pressure between the V6 model and measured data at locations within the Groningen field is within ±2 bar for all pressure data up to 1-1-2021.

The history-match period was run in (stand-alone) MoReS until the end of calendar year 2020. Genrem-MoReS forecasting starts from 1-1-2021 onwards, where the Latest Estimate (LE) is used to constrain production up to 1-10-2021. This LE is in accordance with the graaddagen formula of the Vaststellingsbesluit for gas-year 2020/2021. The various pressure forecast scenarios therefore have a common starting point at the start of gas-year 2021/2022.

2.4 Forecast Scenarios

As requested in the Expectation Letter (Appendix A), seismic hazard and risk calculations are performed for 2 temperature scenarios. The distribution of production volume over the regions and the forecasted pressure distributions are discussed below.

2.4.1 Regional distribution of volumes

Figure 2-3 compares the distribution of production volume over the regions for the two temperature scenarios, which only differ for gas year 2021/2022. Figure 2-4 shows these distributions over each of the next 5 gas-years. The regional distribution is in line with the outcome of the operational strategy based on daily demand profiles. After April 2022, volumes are equally distributed over the two regions South-East and South-West.

Seismic Hazard and Risk Assessment of Production Profile "GTS raming 2021" for the Groningen field - March 2021

Figure 2-3: Monthly production volume per region for the next 5 gas-years for the average temperature (top) and cold (bottom) scenario. Cold temperature only applies to gas year 2021/2022.

Figure 2-4: Regional distribution of production volume per gas-year for the average temperature (top) and cold (bottom) scenario. Cold temperature only applies to gas year 2021/2022.

2.4.2 Pressure Maps

Figure 2-6 Pressure difference at 01-10-2021 compared to last year's forecast for average temperature and OS2 (pressure HRA21 – pressure HRA20).

13

Figure 2-5 shows the modelled reservoir pressure distribution on 1-10-2021, which is the start of gasyear 2021/2022. This pressure distribution is the common starting point in the two temperature scenarios.

Figure 2-6 plots the difference in pressure on 1-10-2021 compared to last year's forecast (HRA 2020) for average temperature and operational strategy 2. This strategy is comparable to the current operational strategy. Compared to last year's demand estimate, actual production up to 1-1-2021 and estimated production for the remainder of the gas year result in less cumulative production at the start of next gas year on 1-10-2021. This is due to a warmer than average 2020 and additional measures to reduce Groningen production volume. As a result, a positive pressure difference is seen (i.e. higher pressure based on the new estimate including actual production up to 1-1-2021), with a maximum local difference of around 3 bar.

Figure 2-9 shows difference maps for a selection of later years. In the period 2025-2027 the forecast based on the new estimate has a slightly lower pressure in the active production regions as a result of the small additional production volume due to the minimum flow requirement. A small difference (of around 1 bar) can be seen in Borgsweer, due to an update of the water injection forecast. Outside the boundary of the Groningen field some higher pressures are seen in the Warffum and Kielwindeweer fields, since production stops earlier in the updated forecast for these fields. From 2032 onwards the difference in pressure in the Groningen field between the current year and previous year forecast is negligible.

Figure 2-7 shows the pressure distribution on 01-10-2022 for the average temperature scenario, and Figure 2-8 for the cold gas year scenario. Figure 2-10 shows the difference in pressure between the two scenarios at the end of gas year 2021/2022 (top left), and 1, 3, 5, 10, and 20 years later. At the end of gas year 2021/2022 the local pressure difference between the average and cold scenario has a maximum of 3.8 bar. Over time this difference dissipates. Twenty years later a maximum local pressure difference of 0.6 bar remains in the South-East corner of the field.

Pressure maps for subsequent gas years in the average temperature scenario are given in Figure 2-11 (2023-2028), Figure 2-12 (2029-2034), and Figure 2-13 (2035-2050, every 3 years).

Figure 2-7: Reservoir pressure on 01-10-2022 (end of gas year 2021/2022) for average temperature scenario

Figure 2-8: Reservoir pressure on 01-10-2022 (end of gas year 2021/2022) for cold temperature scenario

Figure 2-9: Pressure difference maps for average temperature scenario: pressure HRA 2021 – pressure HRA 2020 (OS2). At end of gas year 2021/2022 (top left) and after 1, 3, 5, 10, and 20 years (bottom right).

Figure 2-11: Pressure distribution at 1st of October 2023-2028 for average temperature scenario. See for colour scale Figure 2-5.

Figure 2-12: Pressure distribution at 1st of October 2029-2034 for average temperature scenario. See for colour scale Figure 2-5.

Figure 2-13: Pressure distribution at 1st of October 2035-2050 (every 3 years) for average temperature scenario. See for colour scale Figure 2-5.

3 Subsidence

In this HRA report for Groningen, subsidence is assessed for the period 2021-2031 for both the gas field and connected aquifers. Ongoing pressure depletion in the subsurface of the areas is driving the subsidence. This chapter presents the forecast of surface subsidence based on "GTS-raming 2021", average temperature and the Operational Strategy as described in Chapter 2 of this report. In a series of updates of the Winningsplan Groningen 2016 (Ref. 8 to Ref. 14), this chapter is an updated version of relevant paragraphs on subsidence.

The study area is defined by the Groningen gas field and the most important connected aquifers surrounding the field (Figure 3-1). These aquifers are:

- The "Southern Lauwerszee Trough (Zuidelijke Lauwerszee Trog)" aquifer located between the Groningen field and the smaller fields of Vries and Roden.
- In the north, the "Mowensteert" aquifer is connected to the Groningen gas field causing possible subsidence in the Waddenzee.
- The Rysum aquifer is connected to the eastern part of the field.
- In the south, an aquifer between Annerveen and Groningen is connected to the Groningen field.

The white coloured aquifers in Figure 3-1, e.g. the Goldhoorn aquifer to the east of the Groningen, have no connection to the gas field due to large offset faults blocking lateral fluid flow and hence preventing pressure communication. The "Noordelijke Lauwerszee trog" is mainly connected to the Bedum and Warffum fields.

Possible depletion in the connected aquifers to the Groningen gas field was the main driver for conducting the Groningen long term subsidence forecast study (Ref. 35) in 2020. The study describes a statistical workflow that defines the most likely subsidence scenario including the quantification of the model uncertainty. Results from this study were also used in Ref. 36.

This chapter in the current HRA report uses the calibrated subsidence scenario and uncertainties from these studies but based on the latest (GTS-raming 2021) pressure forecast. Short summaries per block in the modelling chain will be provided.

The compaction is described in section 3.1 The influence model translates the compaction in the subsurface to the earth's surface and is described in section 3.2.

The calibrated model, the uncertainty estimation and the resulting subsidence forecast are presented in section 3.3 and 3.4.

Figure 3-1 Overview of the most important lateral aquifers attached to the Groningen field. In red the field names that are mentioned in the text.

3.1 Compaction model

The RTCiM model (Ref. 38) was used For the subsidence forecast, as it gives the best match to core deformation experiments when compared to any of the other compaction models. Another advantage of the RTCiM model is that it spans a wide range of temporal behaviours to reflect the possible visco-plastic behaviour of the sandstone. The RTCiM model can behave more linear with depletion or exhibit time decay and temporal characteristics by changing parameter values. None of the other models is as versatile. This choice concurs as well with the findings of the LTS-II research (Ref. 39).

3.1.1 Input to compaction model

Reservoir compaction is mainly dependent on pressure depletion, reservoir thickness and rock compressibility. These parameters will be described in the following sections.

3.1.1.1 Pressure scenario for the reservoir and laterally connected aquifers

The basis for the pressure scenario is the V6 reservoir model which includes a depleting Carboniferous as a separate layer (Chapter 3). Following the results from the Groningen long term subsidence study (Ref. 35), the V6 model also delivers the pressure forecast for the aquifer areas Rysum, Möwensteert, and South (aquifer between Groningen and Annerveen). The aquifer pressures in the Southern Lauwerszee Trough are described by a set of 5 box models. Each box model provides 5 possible pressure realisations. The geodetic measurements above these box models were used to select the most likely combination of these possible realisations. Pressures from this box-model combination was stitched to the V6 model. More information on the workflow and selection procedure for the aquifer realisations can be found in Ref. 35Ref. 15.

3.1.1.2 Reservoir Thickness

A reservoir thickness map from the V6 reservoir model reflecting the net thickness was used as input for the compaction model in the HRA 2020 update (Figure 3-2). The same information is used as well in the HRA 2021 update. Net thickness is specified for both the ROSL and DC.

3.1.1.3 Rock compressibility

Rock compressibility is described by the RTCiM compaction model and the parameter values used for the HRA 2021 forecasts result from the workflow that is described by Ref. 35 and listed in Table 3-1.

| Posterior RTCiM parameters | Value |
|-------------------------------|-------|
| A [-] | 0.85 |
| d [-] | 0.40 |
| b [-] | 0.021 |

Table 3-1, parameter values of the RTCiM Ref. 35

Ref. 35 also investigates the likelihood of possible spatial correlations between the compressibility (C_m) and other subsurface parameters like velocity and porosity. The updated posterior correlation to the porosity showed the highest probability in the workflow and was therefore selected. A map of the prior porosity map and the posterior map (after an inversion step in the workflow) are visualised in Figure 3-3. The value for the DC Cm value was deduced from recent core experiments. These experiments show a range of Cm values from 0.1 to 0.6 10^{-5} bar⁻¹. As no clear relation between compressibility and e.g. the porosity of the samples was observed, we assumed a constant (average) value of 0.3 10^{-5} bar⁻¹ for the DC. (Ref. 37).

Figure 3-3 Left: prior Cm-porosity map. Right: Posterior Cm-porosity map.

3.2 Influence model

The influence model translates the compaction of the reservoir into surface subsidence. In Ref. 39, it was concluded that a thick salt layer above the Ameland reservoir significantly impacts the temporal behaviour of the subsidence. Compared to the Groningen field, the Ameland field is relatively small, where compaction leads to stress arching in the overburden, changing the shear stress above the reservoir. These shear stresses cause creep deformation in the salt resulting in a narrower and more profound subsidence bowl. Due to its large size, stress arching is nearly absent above the Groningen field and therefore it is assumed in this study to neglect salt creep. Still the salt can result in a steeper edge of the subsidence bowl, a phenomenon that already was recognised and described earlier (**Error! Reference source not found.**). We adopted therefore the influence model as described in Ref. 35, that combines a half-space model with a rigid basement (Ref. 40) using a value of 7 km for the rigid basement and a Poisson's ratio of 0.2. The effect of this model results in a change of the bowl shape that is time independent.

3.3 Uncertainty estimation

The uncertainty estimation for the modelled subsidence is described in Ref. 35. The Monte Carlo-Markov Chain procedure calculates for each subsidence scenario the model uncertainty Σ_{emp} that is largely dependent on the modelled subsidence.

The covariance matrix Σ_{emp} is calculated with only having non-zero values on the diagonal of the matrix and uses the following equation to describe the error at a given location:

 $\Sigma_{emp} = \sigma_0 + \alpha \mu_i$

where μ_i is the modelled displacement (double difference) for location *i*. For the most likely scenario, the value for σ_0 of 0.53 and a value of 0.029 for α was calculated in Ref. 35.

3.4 Subsidence forecast

In this section the current status and expected development of subsidence (and uncertainty) up to 1-1-2032 is presented. Subsidence caused by gas production and aquifer depletion from the Groningen field is combined with the effects from ongoing gas production from neighbouring fields as published in Ref. 36.

Figure 3-4 shows the results of the subsidence model in comparison with the measured subsidence in benchmark locations across the gas field for the period 1972-2018.

Figure 3-4 Contours (solid blue lines) of the modelled subsidence between 1972 and 2018 compared to the measurements (green dots with value label) spanning the same period. All values are in cm.

Subsidence forecasts for the end of year 2025, 2031 and 2050 are presented in respectively Figure 3-5, Figure 3-6 and Figure 3-7. The base case is presented by the contour lines while the P95 uncertainty is visualized by the coloured overlay. Note that the uncertainty presented is only based on the subsidence caused by the Groningen field and connected aquifers.

Figure 3-5 Subsidence forecast in cm for the end of 2025 (contours). The colours indicate the P95 uncertainty in the subsidence.

Figure 3-6 Subsidence in cm for the end of 2031 (contours). The colours indicate the P95 uncertainty in the subsidence.

Figure 3-7 Subsidence in cm for the end of 2050 (contours). The colours indicate the P95 uncertainty in the subsidence.

To visualise the match between modelled and measured subsidence over time since the first levelling surveys, a number of plots are presented in Figure 3-8, showing modelled and measured subsidence at various benchmark locations over the Groningen field.

Figure 3-8 Subsidence at benchmark locations: dark grey line is the predicted subsidence, grey is the P95 uncertainty interval, black dots are levelling measurements plus uncertainty, the blue dots are the InSAR measurements.

Appendix B – Glossary of Terms

This appendix contains a glossary of terms used in this report and the documents references in this report. More extensive glossaries for terms used in earthquake studies have been compiled by the USGS:

https://earthquake.usgs.gov/learn/glossary/?alpha=ALL

and at the web-site <u>www.earthquake-report.com</u>.

https://earthquake-report.com/2011/02/15/glossary-of-earthquake-terms-2/

| Term | Explanation |
|-----------------------|--|
| Acceleration | The rate of change of velocity of a reference point. Commonly expressed |
| | as a fraction or percentage of the acceleration due to gravity (g) where g |
| | = 980 cm/s2 (USGS) |
| Accelerogram | The recording of the acceleration of the ground during an earthquake. |
| Building Code | A building code, or building control, is a set of rules that specify the |
| | minimum acceptable level of safety for constructed objects such as |
| | buildings and non-building structures. The main purpose of building |
| | codes are to protect public health, safety and general welfare as they |
| | relate to the construction and occupancy of buildings and structures. A |
| | seismic code, refers to a building code which uses earthquake-resistant |
| | design principles. (USGS - CEDIM) |
| Cold temperature year | The demand for gas is dependent on the weather and especially on |
| | whether the winter will be cold. This is also reflected in the production |
| | required from the Groningen gas field to ensure security of supply. |
| | Therefore a sensitivity is performed in this hazard and risk assessment |
| | where the target year (gas-year 2020/2021) has a cold winter. |
| Earthquake | The expected (or probable) life loss, injury, or building damage that will |
| | happen, given the probability that some earthquake hazard occurs. |
| | Earthquake risk and earthquake hazard are occasionally used |
| | interchangeably. (USGS) |
| Epicenter | The point on the Earth's surface vertically above the point (focus or |
| | hypocenter) in the crust where a seismic rupture nucleates. (EQCanada) |
| Eurocode 8 | The Eurocodes are the current technical standards for structural design |
| | in Europe, and it is now compulsory for the 28 countries in the Eurocode |
| | zone to adopt these. Eurocode 8 specifically deals with earthquake- |
| | resistant design of structures (CEN, 2006). Each country adopting |
| | Eurocode 8 must develop a National Annex to indicate how the code is |
| | implemented; the National Annex for the Netherlands is being |
| | developed. Eurocode 8 uses a standard practice to represent seismic |
| | hazard via PGA maps associated with ground motions having a 10% |
| | probability of exceedance during 50 years, equivalent to 0.2%/year for a |
| | stationary process, or a return period of 4/5-years. |
| Disaggregation | Disaggregation of a Monte-Carlo simulation result is a technique to |
| | determine the range of the factors with the largest impact on the |
| F 1 | simulation result. |
| Fault | A fracture along which there has been significant displacement of the two |
| | sides relative to each other parallel to the fracture. (USGS) |
| Fault Plane | I he surface on which the earthquake movement takes place. (CEDIM) |

| Gas-year | Gas-years are the 12-month period starting at 1st October. The gas-year 2020/2021 is the period from 1st October 2020 up to and including 30st September 2021. Gas-years are used to avoid the high gas demand winter period to be split over two reporting periods. |
|-----------------------|--|
| Geophone | A device that converts ground movement (velocity) into voltage, which may be recorded at a recording station. The deviation of this measured voltage from the base line is called the seismic response and is analysed for structure of the earth. |
| Ground Motion | General term referring to the qualitative or quantitative aspects of |
| (Shaking) | movement of the Farth's surface from earthquakes or explosions. Ground |
| (51101018) | motion is produced by wayes that are generated by sudden slip on a fault |
| | or sudden pressure at the explosive source and travel through the Earth |
| | and along its surface. (USGS) |
| GTS-raming | The hazard and risk assessment is based on a production profile for the |
| | Groningen field. This is based on a prognosis of demand for Groningen |
| | gas prepared by GTS. GTS raming 2020 as made in January 2020. |
| Gutenberg-Richter | Earthquakes appear to follow a pattern through time in terms of no. of |
| | earthquakes vs. magnitude. This is called the Gutenberg-Richter criterion. |
| | (CEDIM) |
| Hazard | Any physical phenomenon associated with an earthquake that may produce adverse effects on human activities. This includes surface |
| | faulting, ground shaking, landslides, liquefaction, tectonic deformation, |
| | tsunami, and seiche and their effects on land use, manmade structures, |
| | and socioeconomic systems. A commonly used restricted definition of |
| | earthquake hazard is the probability of occurrence of a specified level of |
| | ground shaking in a specified period of time. (USGS) |
| Hypocenter | The point within the Earth where an earthquake rupture initiates. Also |
| | commonly termed the focus. (USGS) |
| Individual Earthquake | The individual earthquake risk is the annual risk that an individual is |
| Risk | exposed to in the various structures in or near which this individual is |
| Inside Legal Dersanal | present (see also table 7.1). |
| Pick (II DP) | normanantly procent in a building (See also table 7.1) |
| Liquefaction | seismology, it refers to the loss of soil strength as a result of an increase |
| Liqueraction | in pore pressure due to ground motion. This effect can be caused by |
| | earthquake shaking (IASPEI)The transformation of a granular material |
| | from a solid state into a liquefied state as a consequence of increased |
| | pore water pressures and reduced effective stress. In engineering |
| | The probability of death of a fictional unprotected person who is |
| Local Personal Risk | permanently present in or near a building. This person is thought to be |
| (LPR) | inside the building 99% of the time and outside near the building 1 % of |
| () | the time (See also table 7.1). |
| Local site conditions | A qualitative or quantitative description of the topography, geology, and |
| | soil profile at a site that affect ground motions during an earthquake. |
| | (IASPEI). |
| Nationale Praktijk | This document describes the structural safety of a building in case of |
| Richtlijn: NPR 9998 | earthquake loads. Constructors can use this guideline to calculate how |
| | strong a building must be in order to comply with the seismic safety |
| | standard for buildings used in the Netherlands. |
| Magnitude | A number that characterizes the relative size of an earthquake. |
| | Magnitude is based on measurement of the maximum motion recorded |

| | by a seismograph(sometimes for earthquake wayes of a particular |
|------------------------|---|
| | frequency) corrected for attenuation to a standardized distance. Several |
| | scales have been defined, but the most commonly used are (1) local |
| | magnitude (ML) commonly referred to as Richter magnitude (2) surface |
| | magnitude (ML), commonly referred to as Kichter magnitude, (2) surface- |
| | wave magnitude (IVIS), (3) body-wave magnitude (IVIB), and (4) moment |
| | magnitude (Mw). ML, Ms and Mb have limited range and applicability and |
| | do not satisfactorily measure the size of the largest earthquakes. The |
| | moment magnitude (Mw) scale, based on the concept of seismic |
| | moment, is uniformly applicable to all sizes of earthquakes but is more |
| | difficult to compute than the other types. In principal, all magnitude |
| | scales could be cross calibrated to vield the same value for any given |
| | earthquake, but this expectation has proven to be only approximately |
| | true thus the need to specify the magnitude type as well as its value. An |
| | increase of one unit of magnitude (for example from 4.6 to 5.6) |
| | increase of one unit of magnitude (for example, from 4.0 to 5.0) |
| | represents a 10-fold increase in wave amplitude on a seismogram or |
| | approximately a 30-fold increase in the energy released. In other words, |
| | a magnitude 6.7 earthquake releases over 900 times (30 times 30) the |
| | energy of a 4.7 earthquake - or it takes about 900 magnitude 4.7 |
| | earthquakes to equal the energy released in a single 6.7 earthquake! |
| | There is no beginning nor end to this scale. However, rock mechanics |
| | seem to preclude earthquakes smaller than about -1 or larger than about |
| | 9.5. A magnitude -1.0 event releases about 900 times less energy than a |
| | magnitude 1.0 quake. Except in special circumstances, earthquakes |
| | helow magnitude 2.5 are not generally not felt by humans (LISGS-IASPEI) |
| Mijproad 1500 Lijst | These are the salt E00 buildings that in the advice of the Mijnraad of mid |
| | 2018 had a mean LDD > 10 ⁻⁵ /user |
| | 2018 had a mean LPR > 10 / year. |
| Monte-Carlo Simulation | The Monte Carlo simulation is a simulation technique whereby a physical |
| | process is simulated not once but many times, each time with different |
| | starting conditions. The result of this collection of simulations is a |
| | distribution function that displays the entire area of possible outcomes. |
| Object-related | The Objectgebonden individual earthquake risk is the risk that an |
| Individual Risk | individual dies in a year due to collapse or falling objects (as a result of an |
| | earthquake) of a building in which or in the direct vicinity of which this |
| | person is present. The residence time in/around that building is therefore |
| | taken into consideration (See also table 7.1) |
| Outside Local Personal | The probability of death of a fictional upprotected person who is |
| | nermanently procent near a building (See also table 7.1) |
| RISK | permanentiy present near a bunuing (see also table 7.1). |
| P wave | A seismic body wave that involves particle motion (alternating |
| | compression and extension) in the direction of propagation. (USGS) |
| P wave | A P wave, or compressional wave, is a seismic body wave that shakes the |
| | ground back and forth in the same direction and the opposite direction |
| | as the direction the wave is moving. |
| Peak Acceleration | The highest acceleration in terms of value. (USGS) |
| PGA | The maximum acceleration amplitude measured or expected in a strong- |
| | motion accelerogram of an earthquake. (IASPEI) |
| Primary Wave | See P Wave (CEDIM) |
| Pick | The probabilistic determination of the damages a certain bazard can |
| NON | cause given the existing unhershility leastion and time (UN) |
| | cause given the existing vulnerability, location and time. (ON) |
| Risk Assessment | Definition: A methodology to determine the nature and extent of risk by |
| | analyzing potential hazards and evaluating existing conditions of |
| | vulnerability that together could potentially harm exposed people, |

| | property, services, livelihoods and the environment on which they depend.Comment: Risk assessments (and associated risk mapping) include: a review of the technical characteristics of hazards such as their location, intensity, frequency and probability; the analysis of exposure and vulnerability including the physical social, health, economic and environmental dimensions; and the evaluation of the effectiveness of prevailing and alternative coping capacities in respect to likely risk scenarios. This series of activities is sometimes known as a risk analysis process. (UN/ISDR) |
|-----------------|---|
| Rupture | The instantaneous boundary between the slipping and locked parts of a fault during an earthquake. Rupture in one direction on the fault is referred to as unilateral. Rupture may radiate outward in a circular manner or it may radiate toward the two ends of the fault from an interior point, referred to as bilateral. (USGS) |
| S-wave | An S wave, or shear wave, is a seismic body wave that shakes the ground back and forth perpendicular to the direction the wave is moving. |
| S Wave Velocity | The velocity of a secondary or S wave. Generally measured in m/s. (CEDIM) |
| Secondary Wave | A seismic body wave that involves a shearing motion in a direction perpendicular to the direction of propagation. When it is resolved into two orthogonal components in the plane perpendicular to the direction of propagation, SH denotes the horizontal component and SV denotes the orthogonal component. Also known as S waves and shear waves. (PDC) |
| Seismic hazard | Risk of a certain ground motion occurring at a location (this can be defined by scenario modeling via stochastic catalogues, DSHA, PSHA or other such methods, and can include different types of earthquake effects) (CEDIM) |
| Seismic Risk | See earthquake risk, also the probabilistic risk is the odds of an earthquake occurring and causing damage within a given time interval and region. (EQCanada) |
| Seismic Station | A ground position at which a geophysical instrument is located for an observation. (U-Milwaukee) |
| Seismic Waves | An elastic wave generated by an impulse such as an earthquake or an explosion. Seismic waves may propagate either along or near the Earth's surface (for example, Rayleigh and Love waves) or through the Earth's interior (P and S waves). (USGS) |
| Seismicity | 1) The geographic and historical distribution of earthquakes. 2) A term introduced by Gutenberg and Richter to describe quantitatively the space, time, and magnitude distribution of earthquake occurrences. Seismicity within a specific source zone or region is usually quantified in terms of a Gutenberg-Richter relationship. (ICWGroup/IASPEI) |
| Seismogram | A record written by a seismograph in response to ground motions produced by an earthquake, explosion, or other ground-motion sources. (ICW Group) |
| Seismometer | A seismometer is a damped oscillating mass, such as a damped mass- spring system, used to detect seismic-wave energy. The motion of the mass is commonly transformed into an electrical voltage. The electrical voltage is recorded on paper, magnetic tape, or another recording medium. This record is proportional to the motion of the seismometer mass relative to the Earth, but it can be mathematically converted to a |

| | record of the absolute motion of the ground. Seismograph is a term that refers to the seismometer and its recording device as a single unit. (NASA) | | |
|----------|---|--|--|
| Velocity | In reference to earthquake shaking, velocity is the time rate of change of ground displacement of a reference point during the passage of earthquake seismic waves commonly expressed in centimeters per second. (USGS) | | |
